

FA_1-DSC1105

The plots for the NKG2A column reveal a clear bimodal distribution, characterized by two distinct peaks. The histogram displays a sharp, smaller peak near zero, representing a "negative" population that lacks expression of the marker, while a larger, broader peak centered around 4 represents the "positive" population. The distinct valley separating these two peaks, also visible as a flattened region in the ECDF curve, confirms that the dataset contains two biologically distinct cell subsets regarding NKG2A expression rather than a single uniform population.

The Q-Q plot comparing CD56 and CD16 reveals that the two markers have significantly different distributions, as evidenced by the blue data points deviating clearly from the red diagonal reference line ($y=x$). The points form a curve that stays largely below the red line, indicating that for the same quantile, the expression values of CD56 (x-axis) are generally higher than those of CD16 (y-axis). This non-linear pattern suggests differences in both the spread and the intensity of expression between the two markers, confirming that they represent distinct biological subpopulations with unique expression profiles rather than a single uniform distribution.
